June 13, 1955

Now that K mesons are available in large numbers from proton [illegible] trons, experiments will soon yield precise values for the lifetime, or [illegible] times, of the K mesons. Exposures of emulsions to K particles have [illegible] made by several groups at Berkeley, under quite different conditions [illegible] as distance from the target and magnetic resolution are concerned. [illegible] knew the relative integrated currents on the targets for exposures with [illegible] and short flight paths, and if geometrical and resolution factors were [illegible] taken into account, these experiments would yield a lifetime. Until [illegible] such an intercomparison of the results has appeared impossible. [illegible] has now been found to tie the results of the various experiments together [illegible] note describes the method and presents the lifetime so determined.

The earliest exposures[1,2] were made in a re-entrant well with [illegible] magnetic resolution, 90° to the target at a distance of about 11 1/2 inches. One set of exposures was carried out in a well which had a 0.1-inch aluminum window and another in a well which had 1-inch aluminum window. Later [illegible] was done at a distance of about 106 inches from the target with magnetic [illegible] tion.[3] The "well exposures" yielded a total of 10 τ mesons from all [illegible] in the laboratory. All groups tabulated the number of K_L and τ mesons [illegible] ping at a range corresponding to a momentum of about 350 ± 15 Mev/c, [illegible] number of all τ mesons stopping at the same range. We have also [illegible] in the stack exposed in the well that had a 0.1-inch aluminum window [illegible] number of 350 ± 15 Mev/c protons and the number of π mesons that [illegible] at the range corresponding to 350 ± 15 Mev/c K mesons. In the well [illegible] silver, lead, and brass targets were used. The ratio of stopped [illegible] protons, determined in the above exposures, was independent of the [illegible] The measurements of this ratio cannot be done for the exposure [illegible] that had the 1-inch aluminum window, since the desired protons stop [illegible]

[illegible]

a total of about 60 τ mesons from all groups in the laboratory [illegible] the ratio of τ mesons to protons of 350 Mev/c at two distances (time of flight - slowing-down time: 1.8×10^{-9} second and 1.3×10^{-8} second, respectively), which yields a mean life for the τ mesons of

$$\tau_\tau = 1.6 \, {}^{+1.2}_{-0.7} \times 10^{-8} \text{ second.}$$

The main contribution to the rms error comes from the small number of τ mesons (10) found in the well exposure.

Unfortunately, the lifetime of the K_L^{mesons} as determined by this method is not trustworthy, even though the statistics are better. The difficulty is that we do not know the scanning efficiency for K_L mesons for the method of scanning used in the well exposure. The efficiency for τ mesons can be assumed to be greater than 0.9, since the τ-meson decay is so easily distinguished.

We wish to thank Dr. Harry H. Heckman and the Richman group for making some of their unpublished results available to us.

This work was done under the auspices of the U.S. Atomic Energy Commission.
